

# What is bioluminescence?

KS2

KS3

Ages 7-14 ⌚ 2 min read

The deep ocean is pitch black — sunlight can't reach it. Yet if you could somehow watch it, you'd see lights flickering and glowing everywhere. Creatures hunting, luring, communicating, and hiding — all using light they make themselves. This living light is called **bioluminescence**, and it's one of the most extraordinary things in nature.

## How living things make light

Bioluminescence is produced by a chemical reaction. Inside the animal's body, a molecule called **luciferin** reacts with oxygen in the presence of an enzyme called **luciferase**. This reaction releases energy — but instead of releasing it as heat (like most chemical reactions), it releases it almost entirely as light. It's sometimes called "cold light" because it generates almost no warmth.

Think of a glow stick. You snap it, two chemicals mix together, and it glows — no battery, no heat, just chemistry turning into light. Bioluminescent animals have their own version of this built directly into their cells, and some can switch it on and off at will.

## Who does it?

Bioluminescence has evolved independently at least 50 separate times in nature — which tells you it must be extraordinarily useful. You'll find it in:

- **Deep-sea fish** — including the terrifying anglerfish, which dangles a glowing lure to attract prey in the darkness
- **Fireflies** — which use flashing patterns to find mates on summer evenings
- **Plankton** — tiny organisms that glow when disturbed, sometimes making entire waves glow blue at night
- **Glowworms** — found in caves in New Zealand, they use threads of glowing silk to trap insects
- **Some fungi and bacteria**

## Why bother glowing?

Different species use bioluminescence for different reasons. Some use it to attract prey (the anglerfish). Some use it to confuse or startle predators — certain squid squirt bioluminescent ink as a decoy. Some use it for communication, like fireflies signalling for mates. Some deep-sea creatures use it for **counter-illumination** — glowing on their undersides to match the faint light from above, making themselves invisible to predators looking up from below.

## In medicine and science

Bioluminescence has become one of the most useful tools in biological research. Scientists attach the genes for luciferase to other genes they want to track — so whenever that gene activates in a cell, the cell glows. It's given researchers an extraordinary window into how cells work, how cancers spread, and how drugs behave inside living tissue.
